Macroscopic domain
Interfacial or domain front energy
Effects of lengths and interface orientation

A B S T R A C T

Under tension or tension/torsion combined loading, the formation and movement of macroscopic interfaces (domain fronts which separate the austenite and martensite regions) in the phase transition of a bulk fine-grained polycrystalline NiTi shape memory alloy (SMA) bar or tube specimen are well-observed phenomena. The interfacial energy of the macroscopic domain front, i.e., the energy per unit area of the front (interface), competes with the bulk energy of the system and plays an important role in understanding and modeling both equilibrium and non-equilibrium domain patterns. This paper investigates the physical origin of the interfacial energy of a planar interface and its orientation and length scale dependences in a bar structure. The energetics of a martensite domain with such a planar interface is quantified by using an elastic inclusion model. We show that the strain energy due to the presence of the martensite domain consists of two parts, the bulk energy (such as from bending) due to the constraints at the bar ends and the localized energy due to the mismatch between the spontaneous transformation strain of the domain and the surrounding austenite. The latter is stored around the domain front and is named as the interfacial energy (domain front energy). It is proved that the interface or the domain front of the bar prefers the orientation that minimizes the system total energy. This is supported by comparison with the experimental observation. The dependences of the interfacial energy on the bar geometry (bar thickness and width), the transformation strain and the interface orientation are quantified.

1. Introduction

The interfaces and their motion are widely observed in phase transformations in metals and ceramics such as the formation of dendrites in supercooled liquids (the molten material) and precipitates in alloys. The formation of an interface takes place by a nucleation process of a new phase from its parent phase. The interfacial energy, i.e., the energy per unit area of the interface, is one of the most important quantities that affect the development of morphology and evolution of microstructure (Porter et al., 2009). For example, the variation of interface configuration (i.e., its orientation and area) and therefore the energy provides the driving force for many important kinetic processes of structure changes such as the formation of equilibrium microstructures, from twin structures, the shape of a grain to the macroscopic domain patterns in a polycrystal. NiTi shape memory alloy (SMA) is a typical material which can undergo diffusionless and displacive martensitic phase transformation and has many important applications. Extensive experimental researches have been performed on the deformation behavior of fine-grained polycrystalline NiTi SMAs (among many others, see Shaw and Kyriakides, 1997, 1998; Shaw, 2000; Zhang et al., 2010; Zhou, 2011 for bars, and see Li and Sun, 2002; Sun and Li, 2002; Feng and Sun, 2006; Zhou, 2011; Zhou and Sun, 2011 for tubes). For superelastic NiTi bars and tubes under stretching, a basic phenomenon of the deformation is the collective and localized phase transformation of the material and the resultant formation of macroscopic deformation domains as shown in Fig. 1. The low-strain (austenite) and high-strain (martensite) regions are separated by “sharp” interfaces (domain fronts) which orientate at about 35° to the transverse axis in a bar (see Fig. 1(a)) and at the middle part of the helix in a tube (see Fig. 1(b)). The high-strain domain consists of almost fully transformed grains whose statistical average transformation strains are 5% in axial direction and ~2.5% in the other two directions (Li and Sun, 2002; Feng and Sun, 2006). The aforementioned interface orientation corresponds to the “invariant-line” on the bar or tube surface along which there is no in-plane misfit. Due to strong incompatibility of the deformation, the interface...
Domain morphology and the interface (domain front) orientations in ultrafine-grained polycrystalline shape memory alloys under tensile stress: (a) the parallelogram domains in a strip geometry, (b) the helical domains in a tube geometry, (c) a cylindrical domain with branched fronts in a tube geometry.

The objective of this paper is to study the interface structure and to define the interfacial energy of macroscopic domains in polycrystalline NiTi shape memory alloys by using a local (inclusion) model. We focus on the energetics of a martensite domain with a single planar interface in bars of different length, width and thickness and aim to clarify the physical origin of the interfacial energy and quantify its length and orientation dependence. The paper is organized as follows. In Section 2, the physical origin of interfacial energy is discussed by an analysis of strain compatibility at the interface (domain front). In Section 3, the equilibrium (or energy minimized) domain and its
interface orientation are determined by means of finite element computation and compared with experimental data. In Section 4, the approximate expression of interfacial energy is derived and its length dependence is quantified. In Section 5, the orientation dependence of interfacial energy is discussed. The summary and conclusions are given in Section 6.

2. Strain mismatch and interfacial energy

During the phase transformation of polycrystalline NiTi shape memory alloys, the formation of new martensitic phase in some macroscopic region of initial austenite phase is accompanied by a change in the shape of this region, which can be represented by a symmetric transformation strain \( \varepsilon^s_{ij} \). Due to the constraint of the initial phase, the new phase tends to choose a certain preferred shape and orientation (Roitburd, 1969, 1974, 1978; Boyko et al., 1994). In this section, we shall present the strain mismatch between these two phases and the resultant interfacial energy.

The problem consists of finding displacement \( u_i \), strain \( \varepsilon_{ij} \) and stress \( \sigma_{ij} \) at an arbitrary point \( x_j \) inside the solid. The total strain \( \varepsilon_{ij} \) is regarded as the sum of elastic strain \( \varepsilon^e_{ij} \) and transformation strain \( \varepsilon^p_{ij} \):

\[
\varepsilon_{ij} = \varepsilon^e_{ij} + \varepsilon^p_{ij},
\]

where \( \varepsilon^e_{ij} = (u_i + u_j)/2 \) with \( u_j = d u_i/d x_j \).

We assume that during the phase transformation the displacements at all points of the solid are continuous and the total strains are compatible. The condition of compatibility of strains at any point inside the solid (St. Venant condition) can be expressed in the following form (Roitburd, 1978; Mura, 1987; Boyko et al., 1994):

\[
R_{ij} = \varepsilon^{lm}_{ij} \varepsilon^{lp}_{mq} \varepsilon_{mq, lp} = 0,
\]

where \( \varepsilon_{ij}^{lm} \) is the permutation tensor. The tensor \( R_{ij} \) is known as the incompatibility tensor.

The gradient term \( \varepsilon_{mq, lp} \) is continuous inside each phase but discontinuous at the interface between the two phases. The jump across the interface can be written as

\[
[\varepsilon_{mq, lp}] = \varepsilon_{mq, lp}^{\text{(austenite)}} - \varepsilon_{mq, lp}^{\text{(martensite)}} = [\varepsilon_{mq}] \hat{n}_i \hat{n}_p,
\]

where \( [\varepsilon_{mq}] = \varepsilon_{mq, lp}^{\text{(austenite)}} - \varepsilon_{mq, lp}^{\text{(martensite)}} \) is the jump magnitude of the total strain and \( \hat{n}_i \) is a unit vector along the normal to the investigated part of the interface.

For those points located at the interface, the strain compatibility condition in Eq. (2) can be shown as:

\[
[R_{ij}] = \varepsilon^{lm}_{ij} \varepsilon^{lp}_{mq} [\varepsilon_{mq}] \hat{n}_i \hat{n}_p = 0.
\]

Substituting Eq. (1) into Eq. (4), we have

\[
[R^i_{lj}] = \varepsilon^{lm}_{ij} \varepsilon^{lp}_{mq} \varepsilon_{mq, lp} \varepsilon_{pq} \hat{n}_p \hat{n}_p = \varepsilon^{lm}_{ij} \varepsilon^{lp}_{mq} \varepsilon_{mq, lp} \varepsilon_{pq} \hat{n}_p \hat{n}_p,
\]

with

\[
[R^i_{11}] = \varepsilon^{33}_{11} n_2^2 + \varepsilon^{33}_{22} n_2^2 - 2 \varepsilon^{23}_{12} n_3 n_2,
\]
\[
[R^i_{22}] = \varepsilon^{33}_{22} n_2^2 + \varepsilon^{33}_{33} n_3^2 - 2 \varepsilon^{13}_{23} n_1 n_3,
\]
\[
[R^i_{33}] = \varepsilon^{33}_{33} n_3^2 + \varepsilon^{33}_{11} n_1^2 - 2 \varepsilon^{12}_{23} n_2 n_1,
\]
\[
[R^i_{12}] = \varepsilon^{23}_{12} n_2 n_3 + \varepsilon^{23}_{12} n_3 n_2 - \varepsilon^{33}_{33} n_1 n_2 - \varepsilon^{33}_{33} n_2 n_1,
\]
\[
[R^i_{13}] = \varepsilon^{13}_{23} n_1 n_3 + \varepsilon^{13}_{23} n_2 n_3 - \varepsilon^{23}_{23} n_2 n_1 - \varepsilon^{23}_{23} n_3 n_2,
\]
\[
[R^i_{23}] = \varepsilon^{13}_{23} n_1 n_3 + \varepsilon^{13}_{23} n_2 n_3 - \varepsilon^{23}_{23} n_2 n_1 - \varepsilon^{23}_{23} n_3 n_2.
\]

A simple geometrical interpretation may be given to Eq. (4). The preservation of the coherency on the interface means that each vector \( \mathbf{X} \) that connects some two points on the interface before the phase transformation passes into the same vector after the phase transformation, regardless with which contacting phase it is considered to belong, i.e.,

\[
[u_{ij}] \mathbf{X}_j = 0,
\]

where \( u_{ij} \) is the displacement gradients (total distortions) of the contacting phases relative to the initial single-phase state. If we consider a plane interface element with the normal \( n_i \), then \( X_j n_j = 0 \) and the requirement for the preservation of the contact in Eq. (6) is fulfilled if

\[
[u_{ij}] = s \hat{n}_i,
\]

where \( s \) is the magnitude of the jump to be determined. \( [u_{ij}] \) describes the distortion with an invariant plane. All the planes with the normal \( n_i \) are not distorted since the displacements in each plane are the same, \( u_i = s \hat{x}_i \), \( x_i \) being the distance of the plane from the interface. Under the condition in Eq. (7), the relative strain of the contacting phases is reduced to a simple shear and a normal displacement of the stack of planes parallel to the interface.

The compatibility preservation condition in Eq. (7) can be reduced to definite restrictions on permissible strain discontinuity and disorientation:

\[
[e_{ij}] = \left[ e^e_{ij} \right] - \left[ e^p_{ij} \right] = \frac{1}{2} \left( s \hat{n}_j + s_j \hat{n}_i \right),
\]

\[
[\omega_{ij}] = \left[ \omega^e_{ij} \right] - \left[ \omega^p_{ij} \right] = \frac{1}{2} \left( s \hat{n}_j - s_j \hat{n}_i \right),
\]

where \( \omega_{ij} \) is the antisymmetric parts of the transformation strain which is taken as zero in our study. The rotation jump (in addition to the transformation strain) of a domain in a long strip in tension creates a slight misalignment (kinking) with the loading axis and thus causes bending (Corona et al., 2002) and it is ignored here for the purpose of simplicity of mathematical analysis. The effect of kinking on energetics is definitely worth investigation in the future work. The strain discontinuity in Eq. (8) is a solution to the compatibility condition in Eq. (4).

If we have \( e^p_{ij} = -(s \hat{n}_j + s_j \hat{n}_i)/2 \) (or equivalently \( [R^i] = 0 \)), then the two phases contact along a non-distorted common plane (invariant plane) and no elastic strain arises as a result of the contact of phases (see Fig. 3). On the contrary, the deviation of transformation strain discontinuity from the invariant plane defines the degree of mutual elastic phase distortions and gives rise to internal stresses. In other words, it is the interface incompatibility of transformation strain on the interphase boundary that is the source of the internal stresses in a heterophase system. The fields of internal stresses are long range and are spread from the source interface to distances of the order of the boundary extent (the smallest dimension of the object) (Roitburd, 1978). For example, in Dai and Cai (2006) the analytical solution for an infinite slender elastic cylinder under phase transition was presented and it was found that the thickness of the phase boundary is proportional to the radius of the cylinder. But for most general problems, it is extremely challenging to achieve analytical solutions and we have to implement numerical solutions such as finite element simulations.

For most shape memory alloys under tensile loading, the non-zero components are only \( e^e_{11} \), \( e^e_{22} \) and \( e^e_{23} \). Then Eq. (5) can be simplified

\[
e^e_{ij}(M) [\varepsilon_{ij}(M) + e^e_{ij}(A)]
\]

Then

\[
e^e_{ij}(M) [\varepsilon_{ij}(M) + e^e_{ij}(A)]
\]
as:

\[
[R'] = \begin{bmatrix}
\varepsilon_{11}^p + \varepsilon_{22}^p n_2^2 & 0 & 0 \\
-\varepsilon_{11}^p n_2 & \varepsilon_{11}^p + \varepsilon_{22}^p n_3^2 & 0 \\
-\varepsilon_{11}^p n_3 & 0 & \varepsilon_{11}^p + \varepsilon_{22}^p n_3^2 \\
-\varepsilon_{22}^p n_2 & 0 & 0 \\
-\varepsilon_{22}^p n_3 & 0 & 0 \\
\varepsilon_{22}^p n_2 & 0 & 0 \\
\varepsilon_{22}^p n_3 & 0 & 0 \\
\varepsilon_{22}^p n_3 & 0 & 0 \\
\end{bmatrix}.
\]

It can be checked that in Eq. (10) there is no specific interface orientation \( n_i \) that can satisfy the condition \( |R'_{ni}| = 0 \). We can expect that the elastic strain and stress field have to appear around the interface to guarantee the compatibility of total strains. As a consequence, it will lead to the interfacial energy stored around the interface.

In previous studies of thin-walled structures like thin-walled tubes (Li and Sun, 2002; He and Sun, 2009a, 2009b, 2009c), only two transformation strain components (\( \varepsilon_{11}^p \) and \( \varepsilon_{33}^p \)) were considered in determining the orientation of the domain front in the \( x_1 \)–\( x_3 \)-plane. The transformation strain \( \varepsilon_{22}^p \) along the wall-thickness direction (\( x_2 \)-axis) was treated separately and considered as the origin of interfacial energy. In this case we can ignore the effect of \( \varepsilon_{22}^p \) and \( n_2 \) in Eq. (10):

\[
[R'] = \begin{bmatrix}
0 & 0 & 0 \\
0 & \varepsilon_{11}^p + \varepsilon_{33}^p n_2^2 & 0 \\
0 & 0 & \varepsilon_{11}^p + \varepsilon_{33}^p n_3^2 \\
0 & 0 & 0 \\
0 & 0 & 0 \\
0 & 0 & 0 \\
0 & 0 & 0 \\
0 & 0 & 0 \\
\end{bmatrix}. \tag{11}
\]

It can be seen that we have \( |R'_{ni}| = 0 \) for two specific orientations \( n_i \) of the “invariant-line” on the \( x_1 \)-\( x_3 \)-plane:

\[
n = \pm \left[ \frac{\varepsilon_{11}^p}{\varepsilon_{11}^p - \varepsilon_{11}^P} \right] \begin{bmatrix} 0 \\ 0 \\ \sqrt{\varepsilon_{33}^p - \varepsilon_{33}^P} \end{bmatrix} \tag{12}
\]

Therefore, the “invariant-line” exists only if \( \varepsilon_{11}^P \) and \( \varepsilon_{33}^P \) have opposite signs (\( \varepsilon_{11}^P > 0 \) \( > \varepsilon_{33}^P \)). The corresponding orientation angle \( \theta \) to the \( x \)-axis can be given as:

\[
\theta = \tan^{-1} \left( \sqrt{\frac{\varepsilon_{11}^p}{\varepsilon_{33}^p}} \right) \text{ or } \theta = \pi - \tan^{-1} \left( \sqrt{\frac{\varepsilon_{11}^p}{\varepsilon_{33}^p}} \right). \tag{13}
\]

For the transformation strain \( \varepsilon_{11}^P = -2.5\% \) and \( \varepsilon_{33}^P = 5\% \) in polycrystalline NiTi shape memory alloys, the orientation angle \( \theta_0 = 35^\circ \). In Li and Sun (2002), the principle of energy minimization was applied to determine the orientation angle of a thin flat ellipsoidal domain in the tube system, and the same interface orientation was found as those in Eqs. (12) and (13).

**Comment 1**: Anisotropy widely exists in most of textured polycrystalline materials. Here we made the assumptions of isotropic transformation strains and isotropic linear elastic austenite and martensite. The purpose is mainly for the simplicity of mathematical analysis. The effects of material anisotropy on the interfacial energy of domain are definitely worth investigation in the future work.

Next, we aim to study the effect of the transformation strain \( \varepsilon_{22}^P (\approx -2.5\%) \) along the wall-thickness direction (\( x_2 \)-axis) and get preliminary understanding of interfacial energy. This target can be achieved by considering a simple plane-stress problem of an infinite long bar in \( x_3 \)-\( x_2 \)-plane with a half (\( x_3 < 0 \)) in austenite phase and the other half (\( x_3 > 0 \)) in martensite phase as shown in Fig. 4. The thickness of the bar (along \( x_2 \)-axis) is \( 2c \). The original problem in Fig. 4(a) can be decomposed into three sub-problems as shown in Fig. 4(b)–(d) and the solutions are given in Appendix A. The distributions of total stresses along \( x_3 \)-axis for those points located at \( x_2 = 0 \) (see Eq. (A11) in Appendix A) can be expressed as

\[
\sigma_{33} = \frac{E \varepsilon_{22}^p}{\pi} \int_0^\infty \sinh k - k \cosh k \sin \left( \frac{\theta_0}{k} \right) dk,
\]

\[
\sigma_{22} = -\frac{E \varepsilon_{22}^p}{\pi} \int_0^\infty \left( 1 - \sinh k + k \cosh k \right) \sin \left( \frac{\theta_0}{k} \right) \frac{\sinh k}{k} dk,
\]

\[
\sigma_{11} = 0. \tag{14}
\]

The variation of stresses \( \sigma_{33} \) and \( \sigma_{22} \) in Eq. (14) along \( x_3 \)-axis is plotted in Fig. 5. It is seen that the stresses are mainly concentrated in a small region (\( |x_3/c| < 1 \)) around the martensite–austenite interface. It is stress free for the regions far away from the interface and therefore they have no contribution to the interfacial energy.
The strain energy due to the presence of the martensite domain (see Eq. (19)). In the finite element modeling, the boundary constraints ¯Ω1 = 11 33 (σ11ε11 + σ22ε22 + σ33ε33)Ω. (19)

Although Eq. (15) is still not very simple, we can see that the elastic strain energy Uel is linearly proportional to the half-width c along x2-axis and this energy is mainly stored around the austenite–martensite interface.

As a summary, it is clearly shown in Eq. (10) that the strain mismatch due to the transformation strain in a polycrystalline NiTi bar cannot be accommodated without elastic strains and therefore the elastic stresses must appear around the interface. Such a localized stress field leads to the interfacial energy (see Eq. (15) as an example) for the macroscopic austenite–martensite interface. This physical picture and origin of the macroscopic interface energy is consistent with the thermodynamic Ginzburg-Landau theory (or Cahn and Hilliard theory) in that the interface zone is in the non-convex region of free energy function and has extra bulk energy than the austenite and martensite phases.

3. Interface orientations in bars under tension

In this section, we shall determine the interface orientations in superelastic NiTi bars under tensile loading. We consider a rectangular bar of a length L having a uniform cross-section (width w and thickness t) as shown in Fig. 6. We assume that half of the bar is transformed into the martensite phase (domain Ω) with a planar austenite–martensite interface located at the center of the bar. The assumption of such a planar interface is motivated by both the experimental observation and the purpose of mathematical simplicity.

Based on the understanding in Section 2, the problem to quantify the interfacial energy can be solved by first determining the two orientation angles (θ1 and θ2) of the austenite–martensite interface (see Fig. 6). The total energy of the system is computed by means of finite element modeling. We aim to find the interface orientation (θ1 and θ2) of an energy minimized configuration for various bar width w and thickness t. For simplicity, we assume the martensite phase and the austenite phase have the same elastic constants (modulus E = 30 GPa and Poisson’s ratio ν = 0.3). The volume change in phase transformation can be ignored and the nonzero components can be written as ε11 = ε22 = −2.5%, ε33 = −2ε11 = 5%.

The Helmholtz free energy of the system under the displacement-controlled boundary conditions can be expressed as (Dong and Sun, 2012):

\[ U_{\text{total}} = U_{\text{chem}} + U_{\text{el}} + U_{\text{ext}}. \] (16)

where \( U_{\text{chem}} \) is the change in chemical free energy, \( U_{\text{el}} \) is the strain energy due to the presence of martensite domain and \( U_{\text{ext}} \) is the extra elastic energy due to the external displacement-controlled stretching.

Taking the stress-free austenite phase as the reference state, the total change in chemical free energy due to the thermo-elastic martensitic transformation is

\[ \Delta U_{\text{chem}} = V_\Omega \Delta \phi(T) = \frac{L}{2} wt \Delta \phi(T). \] (17)

where \( V_\Omega \) is the volume of martensite and \( \Delta \phi(T) \) is the chemical free energy density difference between two phases. It only depends on the temperature T and can be approximated as a linear function of T around the equilibrium temperature \( T_0 \):

\[ \Delta \phi(T) = \phi^M(T) - \phi^A(T) = k(T - T_0). \] (18)

where k is a material constant determined by the experiments.

The strain energy due to the presence of the martensite domain Ω can be expressed as

\[ U_{\text{el}} = \int_\Omega \sigma_{11} \epsilon_{11} dV + \int_\Omega \sigma_{22} \epsilon_{22} dV + \int_\Omega \sigma_{33} \epsilon_{33} dV. \] (19)

The extra elastic energy due to external displacement-controlled loading can be expressed as

\[ U_{\text{ext}} = Lwt \frac{E}{2} \left( \epsilon_{0}^2 \right)^2. \] (20)

where \( \epsilon_{0} \) is the applied nominal strain.

For our problem, the total change in chemical free energy \( \Delta U_{\text{chem}} \) in Eq. (17) is fixed. For a given nominal strain, the extra elastic energy \( U_{\text{ext}} \) in Eq. (21) is also fixed. Therefore, we only need to investigate the strain energy \( U_{\text{el}} \) due to the presence of the martensite domain (see Eq. (19)). In the finite element modeling, the boundary constraints can be set as follows: at the upper surface (z = L), the deformation along the z-axis is forbidden (\( u_z = 0 \)) and especially at the center of the upper surface (x = y = 0, z = L) the deformations along the x- and y-axes are also forbidden due to symmetry (\( u_x = u_y = 0 \)). At the bottom surface (z = 0), the deformations along the x- and y-axes are forbidden due to symmetry (\( u_x = u_y = 0 \)), and the elongation along the z-axis is free (\( u_z \neq 0 \)) and its magnitude is the same for all surface points.

We first choose the bar geometry as L = 20 mm and w = 1 mm. The variation of strain energy \( U_{\text{el}} \) with two orientation angles \( \theta_1 \) and \( \theta_2 \) for four different bar thickness/width ratio (t/w = 0.25, 0.5, 0.75, 1) is shown in Fig. 7. It is seen that the minimum strain energy always occurs at the same orientation angles (\( \theta_1 \approx 35^\circ \) and \( \theta_2 \approx 0^\circ \)). In other words, the interface tends to orient along the “invariant-line” on the front surface (xz-plane) of the bar, while the side-walls of the interface (yz-surface) are always perpendicular to the loading axis (z-axis). It is noticed that for the case of a square
cross-section (with $t/w = 1$), there exists another pair of orientation angles ($\theta_1 \approx 0^\circ$ and $\theta_2 \approx 35^\circ$) corresponding to the minimum total energy due to the symmetry.

Experimental observation of morphologies of austenite–martensite interfaces was conducted for uni-axially stretched NiTi shape memory alloy bars of different aspect ratios ranging from 0.25 to 1. As shown in Fig. 8, the interface on the front surface ($xz$-plane) of each bar oriented at around $35^\circ$ to the $x$-axis, while the interface on the side surface ($yz$-plane) of each bar was always perpendicular to the loading axis ($z$-axis). Such experimental observations agree well with our modeling predications.

As a summary, for long NiTi bars (with $L \gg w$) under stretching, the orientation angles of the interface should always be $\theta_1 = \theta_0 \approx 35^\circ$ and $\theta_2 \approx 0^\circ$.

### 4. Interfacial energy and its length dependence

In this section, we shall derive the approximate expression of the interfacial energy. Based on the analysis and experimental observation in Section 3, we recognize that the two orientation angles of the interface are always $\theta_1 = \theta_0 \approx 35^\circ$ and $\theta_2 \approx 0^\circ$ for long NiTi bars (with $L \gg w$). Therefore, in this section our focus will be on the three length scales (bar length $L$, width $w$ and thickness $t$).

For the cases with displacement-controlled boundary constraints studied in Section 3, the strain energy $U_{el}$ (see Eq. (19)) consists of two parts, the interfacial energy and the bulk bending energy. The interfacial energy is due to the mismatch between the spontaneous transformation strain of the domain and the surrounding austenite and is localized around the domain front (interface), while the bulk bending energy is due to the constraints at the bar ends and is stored throughout the whole bar. To get a clear understanding of the interfacial energy, we first choose different boundary constraints from those in Section 3 to remove the bulk bending energy: at the upper surface ($z = L$), the deformations are totally free ($u_1 \neq 0, u_2 \neq 0, u_3 \neq 0$). At the bottom surface ($z = 0$), the deformations are all forbidden ($u_1 = u_2 = u_3 = 0$).

The variation of the interfacial energy density per unit area $U_{front}/(tw\cos \theta_0)$ with the bar thickness $t$ and width $w$ is shown in Fig. 9. It is seen that the interfacial energy density $\gamma = U_{front}/(tw\cos \theta_0)$ is linearly proportional to the bar thickness $t$ and does not depend on the specific value of the bar width $w$:

$$U_{front} = \gamma \frac{wt}{\cos \theta_0} = C_2 t \frac{wt}{\cos \theta_0},$$  \hspace{1cm} (22)

where $C_2$ is a constant.

From Eq. (22) it is seen that there exists a characteristic length scale $l_{front} \sim t$. To clarify this length scale, the distributions of the normal strain $\varepsilon_{22}$ across the interface along $z$-axis for those points located at $x = y = 0$ are plotted in Fig. 10. It is seen that the length scale $l_{front}$ is linearly proportional to the bar thickness $t$. This confirms...
the statement in Section 2 that the interfacial energy $U_{\text{front}}$ is a local elastic energy stored around the domain front (interface).

From Eqs. (15) and (19), we notice that the transformation strains $\varepsilon_{11}^P$ and $\varepsilon_{33}^P$, show no contribution to the strain energy $U_0$ since the interface orientation $\theta_1 = \theta_0 \approx 35^\circ$ largely reduces the $xz$-plane mismatch. Therefore, we can draw the conclusion that the interfacial energy is fully due to the transformation strain $\varepsilon_{22}^P$ along the bar thickness direction:

$$U_{\text{front}} = -\frac{1}{2} \sigma_{22} \varepsilon_{22}^P V_2. \tag{23}$$

Next, we consider the displacement-controlled loading condition to check if the end constraint and the bar length $L$ contribute to the interfacial energy. The variation of the interfacial energy density per unit area $U_{\text{front}}/(t \cdot \cos \theta_0)$ with the normalized bar length $L/w$ for different normalized bar thickness ($t/w = 0.25, 0.5, 0.75, 1$) are shown in Fig. 11. It is seen that the interfacial energy density $U_{\text{front}}/(t \cdot \cos \theta_0)$ does not depend on the normalized bar length $L/w$, which double confirms our conclusion that the interfacial energy (domain front energy) is a local elastic energy due to the local stress field around the domain front.

The variation of the bending energy $U_{\text{bend}}$ with the normalized bar length $L/w$ for different normalized bar thickness ($t/w = 0.25, 0.5, 0.75, 1$) are shown in Fig. 12. It is seen that the normalized bending energy $U_{\text{bend}}/(t \cdot \cos \theta_0 w)$ is inversely proportional to the normalized bar length $L/w$ and does not depend on the normalized bar thickness $t/w$:

$$U_{\text{bend}} = C_1 \cdot \frac{wt}{\cos \theta_0} \cdot \frac{w^2}{L}. \tag{24}$$

where $C_1$ is a constant. The bending energy $U_{\text{bend}}$ therefore is a bulk elastic energy since it depends on the bar length $L$.

As a summary, for long NiTi bars (with $L \gg w$) under stretching, the interfacial energy (domain front energy) is a local elastic energy due to the local stress field around the domain front. The interfacial energy density $\gamma$ does not depend on the bar length $L$ and width $w$, while it is linearly proportional to the bar thickness $t$.

5. Orientation dependence of the interfacial energy

Recent experiments on a simply supported NiTi shape memory alloy bar under three-point bending (with a concentrated force applied at the center of the bar) demonstrate that there was orientation (the angle $\theta$ to the vertical axis of the bar) evolution of the interface between austenite matrix and quasi-isosceles-triangle shaped martensite domain (see Fig. 13). At the beginning of the martensite domain nucleation, the interface was oriented at about $35^\circ$ (see Fig. 13(a)) to the vertical axis of the bar, similar to the “invariant line” in tension.
Fig. 13. The orientation (the angle to the vertical axis of the bar $\theta$) evolution of the interface between austenite matrix and quasi-isosceles-triangle shaped martensite domain in a simply supported NiTi shape memory alloy bar under three-point bending: (a) $35^\circ$; (b) $38^\circ$; (c) $43^\circ$; (d) $48^\circ$.

Fig. 14. A straight bar of rectangular cross-section under three-point bending. The bar consists of high-strain (martensite) and low-strain (austenite) regions that are separated by planar interfaces.

of bars. For the quasi-isosceles-triangle shaped domain under continued bending, in addition to the upward propagation of the apex, the interfaces gradually rotate which leads to an increase of the orientation angle $\theta$ ($35^\circ \rightarrow 38^\circ \rightarrow 43^\circ \rightarrow 48^\circ$). The martensite domain growth through interface rotation significantly reduced the curvature of bended shape of the transformed zone due to the physical origin of the transformation strain in the longitudinal direction, thus releasing the bending strain energy. From an energetic point of view, the rotation of the interface associated with martensite domain growth can be regarded as the result of the energy minimization principle.

Consider the three-point bending model shown in Fig. 14. We choose the bar geometry as $L = 20$ mm and $h = 1$ mm. For this model, there are two governing parameters: the height $x$ of the martensite domain and the orientation angle $\theta_1$. The total energy of the system is also computed by means of finite element modeling. We aim to find the energy minimized configuration for various given displacement $u$. The phase transformation strain is the same as that for the tensile loading in Section 3 with $\varepsilon_{22}^{p} = -2.5\%$, $\varepsilon_{33}^{p} = -2\varepsilon_{11}^{p} = 5\%$.

The variation of total energy $U_{\text{total}}$ with two governing parameters $x/h$ and $\theta_1$ for four different applied loads ($u/h = 1$, $1.2$, $1.4$, $1.6$) is shown in Fig. 15. For relatively small displacement $u = h$, the energy minimized configuration corresponds to the fully austenite phase. For $u = 1.2h$, the orientation angle $\theta_1$ for the energy minimized configuration is about $35^\circ$. It is seen that this preferred orientation angle $\theta_1$ gradually increases as the applied displacement $u$ increases. At the same time, the height $x$ of the martensite domain also increases as $u$ increases.

When the interface orientation $\theta_1$ deviates from $35^\circ$, the interfacial energy $U_{\text{front}}$ will not only depend on the transformation strain $\varepsilon_{22}^{p}$ along the bar thickness direction (see Eq. (23)), but also will depend on the other two transformation strains ($\varepsilon_{11}^{p}$ and $\varepsilon_{33}^{p}$). To address the orientation dependence of the interfacial energy, we employ the finite element modeling in Section 4 and consider the bar geometry with different $t/w$. The boundary constraints chosen are the same as those in Section 4: at the upper surface ($z = L$), the deformations are totally free ($u_1 \neq 0, u_2 \neq 0, u_3 \neq 0$). At the bottom surface ($z = 0$), the deformations are all forbidden ($u_1 = u_2 = u_3 = 0$). Now there is no bulk bending energy in the bar and the strain energy $U_{\text{el}}$ equals the interfacial energy $U_{\text{front}}$. Under the condition $\theta_2 = 0^\circ$, the variation of the interfacial energy $U_{\text{front}}$ with the orientation angle $\theta_1$ for different

Fig. 15. The variation of total energy $U_{\text{total}}$ with two governing parameters $x/h$ and $\theta_1$ for different applied loads: (a) $u/h = 1$, (b) $u/h = 1.2$, (c) $u/h = 1.4$, (d) $u/h = 1.6$. 
6. Summary and conclusions

The macroscopic interfaces (domain fronts) are commonly observed in the phase transition process of bulk polycrystalline NiTi shape memory alloys under external loading. The understanding and quantification of the interfacial energy are therefore fundamental issues and play important roles in modeling the phase transition process in these materials. In this paper, we studied the energetics of the martensite domain with planar interfaces in a superelastic NiTi polycrystal. The misfit strain energy due to the presence of a martensite domain was quantified numerically by finite element simulation. It was demonstrated that such misfit energy quantification of the interfacial energy are therefore fundamental issues and play important roles in modeling the phase transition process of bulk polycrystalline NiTi.

Appendix A. Solution of inclusion problem

A.1. Sub-problem I

The martensite domain is subject to the traction $p = -E\varepsilon_{zz}^p > 0$ on its upper and bottom surfaces to guarantee there is no deformation of the bar as shown in Fig. 4(b). We have

$$\sigma_{33}^1 = 0, \quad \sigma_{22}^1 = p, \quad \sigma_{32}^1 = 0 \text{ for } x_3 > 0,$$

$$\sigma_{33}^1 = \sigma_{22}^1 = 0 \text{ for } x_3 < 0.$$  \hspace{1cm} (A1)

A.2. Sub-problem II

The infinite long bar is subjected to the distributed pressure $p/2$ on its upper and bottom surfaces as shown in Fig. 4(c). We have

$$\sigma_{33}^\parallel = 0, \quad \sigma_{22}^\parallel = -\frac{p}{2}, \quad \sigma_{32}^\parallel = 0.$$  \hspace{1cm} (A2)
A.3. Sub-problem III

The same infinite bar is subjected to the distributed traction \( p/2 \) on the left side and the distributed pressure \( p/2 \) on the right side as shown in Fig. 4(d). The boundary conditions require that at \( x_3 = \pm c \),

\[
\sigma_{33}^{III} = -\frac{p}{2}, \quad \sigma_{32}^{III} = 0 \quad \text{for} \quad x_3 > 0,
\]

\[
\sigma_{33}^{III} = \frac{p}{2}, \quad \sigma_{32}^{III} = 0 \quad \text{for} \quad x_3 < 0. \tag{A3}
\]

A standard way to solve this problem is to employ Airy’s stress function \( \phi \). The stress components expressed by \( \phi \) are

\[
\sigma_{33} = \frac{\partial^2 \phi}{\partial x_3^2}, \quad \sigma_{32} = \frac{\partial^2 \phi}{\partial x_3 \partial x_2}, \quad \sigma_{31} = -\frac{\partial^2 \phi}{\partial x_3^2} \tag{A4}
\]

where \( \phi \) satisfies the bi - harmonic equation

\[
\frac{\partial^4 \phi}{\partial x_3^4} + 2 \frac{\partial^4 \phi}{\partial x_3^2 \partial x_2^2} + \frac{\partial^4 \phi}{\partial x_2^4} = 0.
\]

In order to satisfy the bi-harmonic equation, the stress function \( \phi \) can be assumed to take the form

\[
\phi = c^2 \int_0^\infty \left[ C_1(k) \cosh \left( \frac{kx_2}{c} \right) + C_2(k) \left( 2 \cosh \left( \frac{kx_2}{c} \right) \right) \sinh \left( \frac{kx_3}{c} \right) \right] \sin \left( \frac{kx_3}{c} \right) dk. \tag{A5}
\]

From Eq. (A4), the stress components can be obtained as

\[
\sigma_{33}^{III} = \int_0^\infty k^2 \left\{ C_1(k) \cosh \left( \frac{kx_2}{c} \right) + C_2(k) \left[ 2 \cosh \left( \frac{kx_2}{c} \right) \sinh \left( \frac{kx_3}{c} \right) \right] \right\} \sin \left( \frac{kx_3}{c} \right) dk,
\]

\[
\sigma_{32}^{III} = -\int_0^\infty k^2 \left\{ C_1(k) \cosh \left( \frac{kx_2}{c} \right) + C_2(k) \left[ 2 \cosh \left( \frac{kx_2}{c} \right) \sinh \left( \frac{kx_3}{c} \right) \right] \right\} \sin \left( \frac{kx_3}{c} \right) dk.
\]

In order to satisfy the lateral boundary condition, the unknown functions should be determined by the following equations:

\[
C_1(k) \cosh k + C_2(k) k \sinh k = \frac{p}{\pi k^2},
\]

\[
C_1(k) \sinh k + C_2(k) (k \cosh k + k \sinh k) = 0. \tag{A7}
\]

by using the relation

\[
\int_0^\infty \frac{\sin \left( \frac{kx_3}{c} \right)}{k} dk = \left\{ \begin{array}{ll}
\frac{\pi}{2} & \text{for} \quad x_3 > 0 \\
0 & \text{for} \quad x_3 = 0 \\
-\frac{\pi}{2} & \text{for} \quad x_3 < 0
\end{array} \right.
\]

From Eq. (A7) we get

\[
C_1(k) = \frac{p}{\pi k^2} \frac{\sinh k + k \cosh k}{\sinh k \cosh k + k}, \quad C_2(k) = -\frac{p}{\pi k^2} \frac{\sinh k}{\sinh k \cosh k + k}. \tag{A8}
\]

Therefore,

\[
\sigma_{33}^{III} = -\frac{p}{\pi} \int_0^\infty \left[ \sinh k - k \cosh k \frac{\sinh \left( \frac{kx_3}{c} \right)}{\cosh \left( \frac{kx_3}{c} \right)} \right] \frac{\sin \left( \frac{kx_3}{c} \right)}{k} dk,
\]

\[
\sigma_{32}^{III} = -\frac{p}{\pi} \int_0^\infty \left[ \sinh k \frac{kx_2}{c} \sinh \left( \frac{kx_3}{c} \right) \right] \frac{\sin \left( \frac{kx_3}{c} \right)}{k} dk.
\]

\[
\sigma_{31}^{III} = -\frac{p}{\pi} \int_0^\infty \left[ \cos \left( \frac{kx_3}{c} \right) \right] \frac{\sin \left( \frac{kx_3}{c} \right)}{k} dk. \tag{A9}
\]

A.4. Superposition

By superposing three sub-problems, the total stresses can be expressed as

\[
\sigma_{33} = \sigma_{33}^{I} + \sigma_{33}^{II} + \sigma_{33}^{III} = -\frac{p}{\pi} \int_0^\infty \left[ \sinh k - k \cosh k \frac{\sinh \left( \frac{kx_3}{c} \right)}{\cosh \left( \frac{kx_3}{c} \right)} \right] \frac{\sin \left( \frac{kx_3}{c} \right)}{k} dk.
\]

\[
\sigma_{32} = \sigma_{32}^{I} + \sigma_{32}^{II} + \sigma_{32}^{III} = -\frac{p}{\pi} \int_0^\infty \left[ 1 - \sinh k \frac{kx_2}{c} \sinh \left( \frac{kx_3}{c} \right) \right] \frac{\sin \left( \frac{kx_3}{c} \right)}{k} dk.
\]

\[
\sigma_{31} = \sigma_{31}^{I} + \sigma_{31}^{II} + \sigma_{31}^{III} = -\frac{p}{\pi} \int_0^\infty \left[ \cos \left( \frac{kx_3}{c} \right) \right] \frac{\sin \left( \frac{kx_3}{c} \right)}{k} dk. \tag{A10}
\]

Specifically when \( x_3 = 0 \), we have

\[
\sigma_{33} = -\frac{p}{\pi} \int_0^\infty \left[ \sinh - k \frac{kx_2}{c} \sinh \left( \frac{kx_3}{c} \right) \right] \frac{\sin \left( \frac{kx_3}{c} \right)}{k} dk,
\]

\[
\sigma_{32} = \frac{p}{\pi} \int_0^\infty \left[ \sinh k \frac{kx_2}{c} \sinh \left( \frac{kx_3}{c} \right) \right] \frac{\sin \left( \frac{kx_3}{c} \right)}{k} dk.
\]

\[
\sigma_{31} = 0. \tag{A11}
\]

The total elastic energy of the bar can be calculated as

\[
U_E = \frac{1}{2} \int \sigma_{ij} \epsilon_{ij} dv
\]

\[
= \frac{E}{\pi} \int_0^\infty \left\{ \int_0^\infty \left[ -\frac{1}{2} \sinh k \frac{kx_2}{c} \sinh \left( \frac{kx_3}{c} \right) \right] \frac{\sin \left( \frac{kx_3}{c} \right)}{k} dk \right\} dx_3. \tag{A12}
\]
